Received: December 2, 2008; Revised Manuscript Received: January 16, 2009

A single-sheeted double many-body expansion potential energy surface is reported for ground-state CH₂ by fitting accurate ab initio energies that have been semiempirically corrected by the double many-body-expansion scaled-external-correlation method. The energies of about 2500 geometries have been calculated using the multireference configuration interaction method, with the single diffusely corrected aug-cc-pVQZ basis set of Dunning and the full valence complete active space wave function as reference. The topographical features of the novel global potential energy surface are examined and compared with other potential energy surfaces.

1. Introduction

Methylene biradical, CH₂, is of interest to both chemists and astrophysicists. The electronic characteristics cause methylene to possess rather unusual chemical and physical properties. The ground state of methylene is a triplet state (\tilde{X}^3B_1) but methylene has also a low-lying singlet excited state (\tilde{a}^1A_1 in C_{2v} symmetry or $1^1A'$ in C_s). This appears as an electrophile and/or a nucleophile, whereas the triplet electronic state possesses radical properties. On the chemical side, methylene is a product of photolysis of diazomethane (CH₂N₂) or ketene (CH₂CO). In the interstellar medium, CH₂ plays an important role in carbon chemistry. Although the molecule has been identified¹ in interstellar space, it is the direct chemical precursor of the widely observed CH radical as well as other carbon-bearing molecules. In addition, CH₂ is thought to be an important link in the photodissociation sequence of cometary methane. Specifically, CH₄ photodissociates into CH₂, which in turn can photodissociate into CH + H or C + H₂. Of all species in this sequence, only CH has been observed. Studies on CH and CH₄ have been done in detail, with the largest uncertainty lying on the CH₂ photodissociation rate constant and branching ratio to CH + H or C + H₂.

Despite the great interest of the methylene radical in astrophysics and the chemistry of hydrocarbons combustion, there has been limited studies on the potential energy surface (PES) of the lowest (first) singlet state of methylene. However, the ground triplet state of methylene has been widely studied. Theoretically, the most accurate calculations to date on the triplet methylene PES have been conducted by Kalemos et al.² and Comeau et al.³ The former² examines four states (\tilde{X}^3B_1 , \tilde{a}^1A_1 , \tilde{b}^1B_1 , \tilde{c}^1A_1) of the CH₂ molecule using state-of-the-art ab initio methods and basis sets and provides clues to understand both the geometric and electronic structure of those states. The other by Comeau et al.³ has focused on the minimum to extract the ro-vibrational energy levels of the ground and first excited states of methylene radical. Concerning the global PESs involved in the reaction $C(^3P) + H_2(^1\Sigma_g^+) \rightarrow CH(^2\Pi) + H(^2S)$, heretofore labeled as R1, a three-dimensional (3D) PES has been built for the triplet state of CH₂ by Knowles et al.⁴ but their study did not attempt to describe the conical intersections between 3B_1

and 3A_2 PESs for geometries with C_{2v} symmetry, both of $^3A''$ symmetry in C_s . They have reported a C_{2v} barrier for $C(^3P) + H_2$ insertion of ~ 70 kcal mol⁻¹ and a C_s barrier of ~ 40 kcal mol⁻¹. The former result contrasts with the finding of Harding et al.⁵ who found a small barrier for the insertion reaction due to the conical intersection between the two triplet surfaces. This is responsible for changing the lowest energy mechanism for reaction R1 from direct abstraction to insertion.

Concerning the reaction $C(^1D) + H_2(^1\Sigma_g^+) \rightarrow CH(^2\Pi) + H(^2S)$ (R2), a 3D PES has been calculated by Whitlock et al.⁶ based on the valence-bond diatomics-in-molecules (VB-DIM) method. The reaction was predicted to follow a C_{2v} insertion mechanism with no apparent barrier against a 9.7 kcal mol⁻¹ barrier for the collinear abstraction. Blint and Newton⁷ estimated a collinear barrier of 15 kcal mol⁻¹ for abstraction. Later, Bussery-Honvault et al.⁸ computed an adiabatic global PES (heretofore called BHL) for the first singlet state of CH₂. Their surface shows no barrier for the C_{2v} insertion, while a barrier of 12.35 kcal mol⁻¹ is present for the collinear reaction. This value lies between the VB-DIM estimation of Whitlock et al.⁶ and the result of Blint and Newton.⁷

From the experimental side, a wide number of studies^{9–11} have led to the determination of an accurate equilibrium geometry and a local analytical PES for the ground singlet state. However, the wealth of papers concerning the singlet–triplet energy gap shows that this splitting is subject to debate so that these states have been intensively studied both experimentally and theoretically.

Dynamics calculations, using both the quasi-classical trajectory (QCT) and quantum mechanical methods have recently been carried out.^{12–20} A more recent combined experimental and theoretical study on the dynamics of the reaction $C(^1D) + H_2$ has also been reported^{21,22} using the BHL⁸ for the ground singlet state PES. Unfortunately, visible discrepancies were found between the theoretical calculations on the BHL⁸ surface and the experimental results. A possible explanation for these discrepancies is that the $1^1A'$ PES is not accurate enough in the long-range regions.^{21,22} Other explanations are possible though, in particular due to the fact that there are five singlet states that correlate with $C(^1D) + H_2$ in addition to intersections of the conical type involving different electronic states.²³ In other words, nonadiabatic effects may play a significant role.

The purpose of this work is to investigate the major topographical features of the ground singlet state potential

energy surface of methylene by using DMBE^{24–28} theory. Specifically we will employ the single-sheeted DMBE formalism which takes proper account of long-range forces. The paper is organized as follows. Section 2 describes the ab initio calculations carried out in the present work. In section 3, we deal with the analytical representation of the PES. While section 3.1 focuses on the two-body energy terms, section 3.2 concentrates on the three-body ones. The main topographical features of the DMBE potential energy surface are discussed in section 4. The concluding remarks appear in section 5.

2. Ab Initio Calculations

The ab initio calculations have been carried out at the MRCI²⁹ level using the full valence complete active space³⁰ (FVCAS) wave function as reference. Such a FVCAS reference wave function, which involves six correlated electrons in six active orbitals ($5a' + 1a''$), amounts to a total of 50 configuration state functions. For the basis set, we have selected the aug-cc-pVQZ (heretofore denoted by AVQZ) of Dunning,^{31,32} with the calculations being carried out using the Molpro³³ package. About 2500 grid points were chosen to map the potential energy surface of both the C–H₂ and H–CH regions. The former region is defined by $1.0 \leq r_{\text{H}_2}/a_0 \leq 4.0$, $1.2 \leq R_{\text{C-H}_2}/a_0 \leq 10.0$ and $0.0 \leq \gamma/\text{deg} \leq 90$ while, for the H–CH one, we have used a grid defined by $1.5 \leq r_{\text{CH}}/a_0 \leq 4.0$, $1.0 \leq R_{\text{H-CH}}/a_0 \leq 10.0$, and $0.0 \leq \gamma/\text{deg} \leq 180$. For both channels, r , R , and γ define the associated atom–diatom Jacobi coordinates.

All calculated ab initio energies have been subsequently corrected by the double many-body-expansion scaled-external-correlation³⁴ (DMBE-SEC) method to account for excitations beyond singles and doubles and, most importantly, for the incompleteness of the basis set. The total DMBE-SEC interaction energy is then written as

$$V(\mathbf{R}) = V_{\text{FVCAS}}(\mathbf{R}) + V_{\text{SEC}}(\mathbf{R}) \quad (1)$$

where

$$V_{\text{FVCAS}}(\mathbf{R}) = \sum_{\text{AB}} V_{\text{AB,FVCAS}}^{(2)}(R_{\text{AB}}) + V_{\text{ABC,FVCAS}}^{(3)}(R_{\text{AB}}, R_{\text{BC}}, R_{\text{AC}}) \quad (2)$$

$$V_{\text{SEC}}(\mathbf{R}) = \sum_{\text{AB}} V_{\text{AB,SEC}}^{(2)}(R_{\text{AB}}) + V_{\text{ABC,SEC}}^{(3)}(R_{\text{AB}}, R_{\text{BC}}, R_{\text{AC}}) \quad (3)$$

and $R = \{R_i\}$ ($i = 1–3$) defines the set of interatomic coordinates. In turn, the first two terms of the SEC series expansion assume the form

$$V_{\text{AB,SEC}}^{(2)}(R_{\text{AB}}) = \frac{V_{\text{AB,FVCAS-CISD}}^{(2)}(R_{\text{AB}}) - V_{\text{AB,FVCAS}}^{(2)}(R_{\text{AB}})}{F_{\text{AB}}^{(2)}} \quad (4)$$

$$\frac{V_{\text{ABC,SEC}}^{(3)}(R_{\text{AB}}, R_{\text{BC}}, R_{\text{AC}}) = \frac{V_{\text{ABC,FVCAS-CISD}}^{(3)}(R_{\text{AB}}, R_{\text{BC}}, R_{\text{AC}}) - V_{\text{ABC,FVCAS}}^{(3)}(R_{\text{AB}}, R_{\text{BC}}, R_{\text{AC}})}{F_{\text{ABC}}^{(3)}} \quad (5)$$

Following previous work,³⁴ the $F_{\text{AB}}^{(2)}$ parameter in eq 4 has been chosen to reproduce the bond dissociation energy of the corresponding AB diatomic, while $F_{\text{ABC}}^{(3)}$ has been estimated as the average of the two-body F factors. Such a procedure leads to the following values: $F_{\text{HH}}^{(2)} = 0.9773$ and $F_{\text{CH}}^{(2)} = 0.9098$, and $F_{\text{CHH}}^{(3)} = 0.9323$. Note that the calculated scaling factors are close

to unit, which is accepted as a good requirement for the method to yield accurate results.

3. Single-Sheeted Potential Energy Surface

Following early developments by Murrell and Carter,³⁵ we have recently suggested³⁶ a switching function formalism to approximate a multivalued potential energy surface by a single-sheeted form. For the title system, the spin-spatial Wigner–Witmer rules predict the following dissociation scheme

Clearly, a proper description of the potential energy surface would imply the use of a multisheeted formalism due to the occurrence of two electronic states for the carbon atom. Since we are mostly interested in the dissociation channel of $\text{CH}_2(1^1A')$ into $\text{H}_2(1^1\Sigma_g^+) + \text{C}(1D)$, and $\text{CH}(2^2\Pi)$ dissociates into $\text{C}(3P) + \text{H}(2S)$, one must use a function that switches off the $\text{C}(3P)$ state in the $\text{C} + \text{H}_2$ dissociation channel. For this purpose, we have suggested³⁶ the form

$$h(R_1) = \sum_{i=1}^2 \{1 - \tanh[\alpha_i(R_1 - R_1^{i0}) + \beta_i(R_1 - R_1^i)^3]\} \quad (7)$$

where R_1 represents the H–H distance, and α_i and β_i ($i = 1, 2$) are parameters to be calibrated from the ab initio energies such as to control the $\text{C}(1D-3P)$ decay with increasing H–H distance (see the left panel of Figure 1). A major advantage of this switching formalism over the one originally proposed by Murrell and Carter³⁵ is that it leads to a unique set of electronic states at the three-atom asymptote.

In order to get a smooth three-body energy term, we multiply $h(R_1)$ by an amplitude function that annihilates eq 7 at short-range regions (small C–H₂ distances)

$$g(r_1) = \frac{1}{2} \{1 + \tanh[\alpha(r_1 - r_1^0)]\} \quad (8)$$

where r_1 is the distance of C to the center of mass of H₂. The parameters in $g(r_1)$ have been chosen so as to diminish any abrupt switching behavior in the short-range part (see right-hand-side panel of Figure 1). The complete switching function has the form

$$f(\mathbf{R}) = g(r_1)h(R_1) \quad (9)$$

with the numerical values of the parameters in eqs 7–9 being collected in Table 1.

Within DMBE theory, the total potential energy function is expressed as

$$V(\mathbf{R}) = V_{\text{C}(1D)}^{(1)}f(\mathbf{R}) + \sum_{i=1}^3 [V_{\text{EHF}}^{(2)}(R_i) + V_{\text{dc}}^{(2)}(R_i)] + [V_{\text{EHF}}^{(3)}(\mathbf{R}) + V_{\text{dc}}^{(3)}(\mathbf{R})] \quad (10)$$

where $V_{\text{C}(1D)}^{(1)}$ is the energy (at the scaled AVQZ level) difference between $\text{C}(1D)$ and $\text{C}(3P)$ electronic states, namely, $V_{\text{C}(1D)}^{(1)} = 0.046604E_h$. The following sections give the details of all other analytical energy terms in eq 10.

3.1. Two-Body Energy Terms. The potential energy curves of CH and H₂ have been obtained using the extended Hartree–Fock approximate correlation energy method for diatomic molecules, including the united atom limit³⁷ (EHFACE2U)

Figure 1. Switching function used to model the single-sheeted CH_2 DMBE potential energy surface. Shown in the left panel is the fit of the $h(R_1)$ switching form to the ab initio points calculated for $\text{C} + \text{H}_2$ as a function of H–H distance (R_1). Shown in the right-hand side panel is a perspective view of the global switching function in eq 9.

TABLE 1: Parameters in the Switching Function of Equations 7–9

α_1	0.571350
α_2	0.705610

R_1^{10}	2.315740
R_1^{11}	4.689200
R_1^{20}	3.846300
R_1^{21}	5.714090
α	0.75
r_1^0	5.5

which shows the correct behavior at the asymptotic limits. They assume the general form³⁷

$$V(\mathbf{R}) = V_{\text{EHF}}(\mathbf{R}) + V_{\text{dc}}(\mathbf{R}) \quad (11)$$

where EHF refers to the extended Hartree–Fock type energy and dc is the dynamical correlation energy. This is modeled semiempirically as described³⁸

$$V_{\text{dc}}(R) = - \sum_{n=6,8,10} C_n \chi_n(R) R^{-n} \quad (12)$$

where

$$\chi_n(R) = \left[1 - \exp\left(-A_n \frac{R}{\rho} - B_n \frac{R^2}{\rho^2}\right) \right]^n \quad (13)$$

In eq 13, A_n and B_n are auxiliary functions^{24,25} defined by $A_n = \alpha_0 n^{-\alpha_1}$ and $B_n = \beta_0 \exp(-\beta_1 n)$ where α_0 , α_1 , β_0 , and β_1 are universal dimensionless parameters for all isotropic interactions: $\alpha_0 = 16.36606$, $\alpha_1 = 0.70172$, $\beta_0 = 17.19338$, and $\beta_1 = 0.09574$. In turn, $\rho = 5.5 + 1.25R_0$ is a scaling parameter, $R_0 = 2(\langle r_A^2 \rangle^{1/2} + \langle r_B^2 \rangle^{1/2})$ is the LeRoy³⁹ parameter for onset the undamped R^{-n} expansion, and $\langle r_X^2 \rangle$ is the expectation value of the square radius for the outermost electrons of atom X ($X = \text{A}, \text{B}$).

The exponentially decaying part of the EHF type energy is represented by the general form

$$V_{\text{EHF}}(R) = -\frac{D}{R} \left(1 + \sum_{i=1}^n a_i r^i \right) \exp(-\gamma r) \quad (14)$$

where

$$\gamma = \gamma_0 [1 + \gamma_1 \tanh(\gamma_2 r)] \quad (15)$$

and $r = R - R_e$ is the displacement from the equilibrium diatomic geometry. In turn, D , a_i , and γ_i ($i = 1, \dots, n$) are

Figure 2. EHFACE2U potential energy curves for $\text{CH}(X^2\Pi)$ and $\text{H}_2(X^1\Sigma_g^+)$. The solid circles correspond to the ab initio points calculated at the present level of theory.

adjustable parameters to be obtained as described elsewhere.^{25,37} Here, we employed the accurate EHFACE2U potential energy function for $\text{H}_2(X^1\Sigma_g^+)$ reported elsewhere.⁴⁰ To get the potential energy curve of $\text{CH}(X^2\Pi)$ in Figure 2 we used the same method,³⁷ and those ab initio points calculated at the same level of theory used for the title system. The numerical values of all parameters for both diatomic potentials are collected in Table 1 of the Supporting Information.

3.2. Three-Body Energy Terms. 3.2.1. Three-Body Dynamical Correlation Energy. The three-body dynamical correlation energy assumes the usual form⁴⁰

$$V_{\text{dc}}^{(3)} = \sum_i \sum_n f_i(R) C_n^{(i)}(R_i, \theta_i) \chi_n(r_i) r_i^{-n} \quad (16)$$

where i labels the I-JK channel associated with the center of mass separation and (r_i, θ_i, R_i) are the Jacobi coordinates corresponding to a specific $\mathbf{R} = (R_1, R_2, R_3)$ geometry of the triatomic system (see Figure 1 of ref 26). Moreover, f_i is a switching function chosen from the requirement that its value must be +1 at $R_i = R_i^e$ and $r_i \rightarrow \infty$ and 0 when $R_i \rightarrow \infty$. The three-body switching function assumes the form $f_i = (1/2)\{1 - \tanh[\xi(\eta R_i - R_j - R_k)]\}$, with corresponding

expressions applying for f_j and f_k . Following a recent proposal⁴¹ to correct the long-range behavior, we adopt $\eta = 6$ and ξ to be equal to $1.0a_0^{-1}$. Regarding the damping function $\chi_n(r_i)$, we still adopt eq 13 but replace R by the center-of-mass separation for the relevant atom–diatom channel. In addition, the value of ρ has been optimized by trial-and-error to get a good asymptotic behavior of the dynamical correlation term, leading to $\rho = 16.125a_0$.

The atom–diatom dispersion coefficients in eq 16, which are given by

$$C_n^{(i)}(R_i) = \sum_L C_n^L(R) P_L(\cos \theta_i) \quad (17)$$

where $P_L(\cos \theta_i)$ denotes the L th Legendre polynomial. The expansion in eq 17 has been truncated by considering of only the coefficients C_6^0 , C_6^2 , C_8^0 , C_8^2 , C_8^4 , and C_{10}^0 ; all other coefficients have been supposed to make insignificant contributions and hence neglected. To estimate the dispersion coefficients we have employed the generalized Slater–Kirkwood formula,⁴² with the dipolar polarizabilities calculated in the present work at the MRCI/AVQZ level of theory. As usual, the atom–diatom dispersion coefficients so calculated for a set of internuclear distances were fitted to the form

$$C_n^{L, A-BC}(R) = C_n^{L, AB} + C_n^{L, AC} + D_M \left(1 + \sum_{i=1}^3 a_i r^i \right) \exp \left(-a_1 r - \sum_{i=2}^3 b_i r^i \right) \quad (18)$$

where $C_n^{L, AB}$, for $L = 0$, are the corresponding diatom dispersion coefficients (see Table 2 of the Supporting Information; for $L \neq 0$ $C_n^{L, AB} = 0$). All parameters and coefficients in eq 18 have been explained elsewhere.⁴¹ The parameters that resulted from such fits are also reported in Table 2 of the Supporting Information, whereas the internuclear dependences of the dispersion coefficients are shown in Figure 3. Note that in $R = 0$ the asymptotic limit for the isotropic component of the dispersion coefficients are fixed in the value for the A–X interaction, with X being the united atom of BC. As noted elsewhere,⁴⁰ eq 16 causes an overestimation of the dynamical correlation energy at the atom–diatom dissociation channels. To correct such a behavior, we have multiplied the two-body dynamical correlation energy for the i th pair by $\prod_{j \neq i} (1 - f_j)$ and correspondingly for the channels j and k . This ensures⁴⁰ that the only two-body contribution at the i th channel is the one of the JK diatom.

Figure 3. Dispersion coefficients for the atom–diatom asymptotic channels of CH₂ as a function of the corresponding internuclear distance of the diatom.

Figure 4. Reference geometries used in the present work for the three-body EHF part of the potential energy surface. See text for details.

3.2.2. Three-Body Extended Hartree–Fock Energy. By removing, for a given triatomic geometry, the sum of the one-body and two-body energy terms from the corresponding DMBE-SEC interaction energies eq 1, which was defined with respect to the infinitely separated ground-state atoms, one obtains the total three-body energy. By further subtracting the three-body dynamical correlation contribution eq 16 from the total three-body energy that is calculated in that way, one obtains the three-body extended Hartree–Fock energy. This will be represented by the following three-body distributed-polynomial⁴³ form

$$V_{\text{EHF}}^{(3)} = \sum_{j=1}^7 P^j(Q_1, Q_2, Q_3) \prod_{i=1}^3 \{1 - \tanh[\gamma_i^j(R_i - R_i^{j, \text{ref}})]\} \quad (19)$$

where $P^j(Q_1, Q_2, Q_3)$ is a sixth-order polynomial form in symmetry coordinates which are defined as usual.^{44–46} Figure 4 displays the reference geometries that define the displacement coordinates used to write the EHF-type polynomials in eq 19. As usual, we obtain the reference geometries $R_i^{j, \text{ref}}$ by first assuming their values coincide with bond distances of the

associated stationary points. Subsequently, we relax this condition via a trial-and-error least-squares fitting procedure. Similarly, the nonlinear range-determining parameters γ_i^j have been optimized in this way. The complete set of parameters amounts to a total of 140 linear coefficients (c_i ; see the definition in the Supporting Information), 21 nonlinear coefficients γ_i^j , and 7 reference geometries $R_i^{j,ref}$. Their optimal numerical values are collected in Tables 3 and 4 of the Supporting Information. A total of 2500 points has been used for the calibration procedure, with the energies covering a range up to 500 kcal mol⁻¹ above the CH₂ global minimum. Table 2 shows the stratified root-mean-squared deviation (rmsd) values of the final potential energy surface with respect to all the fitted ab initio energies. As shown, the fit shows a maximum rmsd of 0.9 kcal mol⁻¹ up to the highest repulsive energy stratum.

4. Features of DMBE Potential Energy Surface

We find no barrier for the C(¹D) insertion into H₂ in the 1¹A' PES of CH₂, although for collinear geometries the DMBE function predicts a barrier height of 13.2 kcal mol⁻¹ with respect to the C(¹D) + H₂ asymptote, which is located at $R_1 = 1.85a_0$ and $R_2 = 2.55a_0$. This result lies between the early theoretical estimates of 9.7⁶ and 15.0⁷ kcal mol⁻¹, while being in fairly good agreement with the most recent theoretical predictions of 12.35 kcal mol⁻¹ (from the BHL⁸ PES) and 12.3 kcal mol⁻¹ (from the RKHS¹³ PES).

The DMBE PES here reported shows a calculated well depth of 180.25 kcal mol⁻¹ for the CH₂ complex, in its lowest singlet state relative to the three atom dissociation limit, also in good agreement with the best theoretical determination of 180.3 kcal mol⁻¹ by Comeau et al.³ Comparing to the BHL⁸ PES calculated with the MR-SDCI method and a LANO (local atomic natural orbital) basis set, the DMBE PES predicts a well depth larger by 2.05 kcal mol⁻¹. Note that the calculated MRCI/AVQZ well depth for the 1¹A' state of CH₂ is 178.66 kcal mol⁻¹, with the Davidson correction (Q) leading to a further increase of 1.12

kcal mol⁻¹. Note further that the scaling of the dynamical correlation using the DMBE-SEC method leads to a well depth of 180.25 kcal mol⁻¹. Furthermore, we have performed computationally expensive MRCI/AV5Z calculations for some selected geometries, having obtained a well depth of 179.19 kcal mol⁻¹. As seen, this is smaller by 0.59 kcal mol⁻¹ than the MRCI(Q) value and 1.06 kcal mol⁻¹ than our estimate based on DMBE-SEC. Since this accounts for the finiteness of both the one electron basis set and CI expansion, it seems appropriate that this method predicts a further lowering of 0.47 kcal mol⁻¹ with respect to the Davidson (Q) correction. We find the potential well in DMBE to be located at $R = 1.3a_0$ and $r = 3.26a_0$, which corresponds to a geometry of C_{2v} symmetry with $R(\text{C-H}) = 2.09a_0$ and $\angle\text{HCH} = 102.4^\circ$. Clearly, these results are in very good agreement with the available experimental⁴⁷ data on CH₂, $R(\text{C-H}) = 2.09a_0$ and $\angle\text{HCH} = 102.4^\circ$. Relative to the entrance channel, the calculated well depth of CH₂ (100.01 kcal mol⁻¹) in Table 3 is seen to be larger by about 10 kcal mol⁻¹ than the early valence-bond prediction of Whitlock et al.⁶ but in good agreement with the more recent predictions of 99.8 kcal mol⁻¹ from BHL⁷ and 99.75 kcal mol⁻¹ from RKHS¹³ PESs.

Table 3 also shows that the harmonic frequencies of the DMBE PES are in good agreement with the calculated raw MRCI/AVQZ values of 2915, 2990, and 1396 cm⁻¹, with the corresponding DMBE-SEC values being 2914, 2994, and 1393 cm⁻¹. In fact, the deviations between the DMBE predicted values and the MRCI ones are smaller (5 cm⁻¹ or less) than the corresponding differences for the BHL and RKHS PESs.

The singlet state minimum is located slightly higher than the triplet ground-state one. The separation between these two states has been widely studied both theoretically⁴⁸⁻⁵¹ and experimentally,^{3,52-54} but the values obtained cover a wide range of energies⁵⁵ (from 874.39 to 3427.61 cm⁻¹) depending on the method employed. We find the calculated MRCI/AVQZ value for T_0 ,

3115.94 cm^{-1} , to be in good agreement with the best experimental determination of^{56,57} $3147 \pm 5\text{ cm}^{-1}$.

Figures 5–10 illustrate the major topographical features of the CH_2 DMBE PES which has been calculated in the present work. Clearly, it has a smooth and correct behavior over the whole configuration space. Figure 6 presents the contour plot of the PES for a fixed internal angle $\angle\text{HCH} = 102.4^\circ$. It shows that the exit channel presents no potential barrier toward dissociation of CH_2 into $\text{CH}(^2\Pi) + \text{H}(^2S)$. Figures 7 and 8 represent the contour plots corresponding to the insertion and abstraction of $\text{C}(^1D) + \text{H}_2$ reaction. Specifically, Figure 8 shows that the potential at collinear geometries rises rapidly up to a barrier of $13.2\text{ kcal mol}^{-1}$. So, the reaction $\text{C}(^1D) + \text{H}_2(^1\Sigma_g^+) \rightarrow \text{CH}(^2\Pi) + \text{H}(^2S)$ is expected to occur mainly via noncollinear configurations. Figure 9 shows energy contours for a carbon $[\text{C}(^1D)]$ atom moving around a ground-state hydrogen molecule, while a corresponding plot for a hydrogen atom moving around CH is presented in Figure 10. The salient features from these plots are some of the most relevant stationary points for the title system. A characterization of their attributes (geometry,

energy, and vibrational frequencies) is reported in Table 3. Also included for comparison are the results that have been obtained from other PESs, ab initio calculations, and experimental spectroscopic measurements.^{6,47,58,59}

The range of barrier heights for linearity in the $1^1A'$ state of CH_2 obtained by ab initio calculation is pretty large,⁶⁰ varying from 8000 to 10000 cm^{-1} . For example, an early calculation⁶¹ using the rigid bender Hamiltonian gave a result of 10000 cm^{-1} while another one employing⁶² the internally contracted MRCI method using a FVCAS with an extended Gaussian basis set and including also the Renner–Teller coupling effect gave a result of 8800 cm^{-1} . Furthermore, a high level ab initio calculation employing³ also the MRCI method with a ANO basis

Figure 9. Contour plot for an C atom moving around a fixed H_2 diatomic in equilibrium geometry $R_1 = 1.401a_0$ which lies along the X-axis with the center of the bond fixed at the origin. Contours are equally spaced by $0.005E_h$, starting at $-0.17E_h$. The dashed lines are contours equally spaced by $0.000075E_h$, starting at $-0.128E_h$.

Figure 10. Contour plot for an H atom moving around a fixed CH diatomic $R_{CH} = 2.12a_0$, which lies along the X-axis with the center of the bond fixed at the origin. Contours are equally spaced by $0.0075E_h$, starting at $-0.287E_h$. The dashed lines are contours equally spaced by $0.000075E_h$, starting at $0.133E_h$.

set but without inclusion of the Renner–Teller coupling gave a barrier height of 9600 cm^{-1} . In turn, the DMBE PES predicts for the barrier to linearity in $1^1A'$ CH_2 (see Figure 11) a height of 9644 cm^{-1} , a value in good agreement with the experimental determination of 9800 cm^{-1} by Duxbury and Jungen⁶³ obtained by fitting a bending potential function to the $(0, \nu_2, 0)$ levels for $\nu_2 = 0-3$ as observed in laser-induced fluorescence (LIF)^{64,65} and low-resolution dispersed fluorescence⁶⁶ experiments.

The isotropic and leading anisotropic potentials are two important quantities for the study of scattering processes in the $1^1A'$ CH_2 PES and are shown in Figure 12. The isotropic average

potential V_0 determines how close on average the atom and molecule can approach each other, while the magnitude of V_2 indicates whether or not the molecule prefers to orient its axis along the direction of the incoming atom: a negative value prefers the collinear approach while a positive one favors the approach through an isosceles triangular geometry.

Finally, preliminary rate constant calculations have been carried out for the reaction $C(^1D) + H_2 \rightarrow CH + H$ by running quasi-classical trajectories on the PES of the present work at a temperature of 298 K. The calculations predict the rate constant to be $(1.34 \pm 0.06) \times 10^{-10}\text{ cm}^3\text{ s}^{-1}$ when the vibrational and

Figure 12. Isotropic (V_0) and leading anisotropic (V_2) components of the C–H₂ interaction potentials, with the diatomic molecule fixed at the equilibrium geometry. Continuous lines represent V_0 and V_2 components of DMBE PES; dash-dot and dashed lines are the corresponding three-body dynamical correlation and EHF parts.

rotational quantum numbers of H₂ are kept fixed at $\nu = 0$ and $j = 0$. This shows good agreement with a recent state-specific quantum dynamics result¹⁶ on the RKHS¹³ surface, $(1.2 \pm 0.6) \times 10^{-10} \text{ cm}^3 \text{ s}^{-1}$, and the experimental⁶⁷ value of $(2.0 \pm 0.6) \times 10^{-10} \text{ cm}^3 \text{ s}^{-1}$. The calculated thermalized rate constant is $(1.09 \pm 0.06) \times 10^{-10} \text{ cm}^3 \text{ s}^{-1}$. Although only slightly off the experimental error bar, we should recall that quantum effects are ignored in the present estimate. A detailed account of the ongoing dynamics calculations will be reported elsewhere.

5. Concluding Remarks

In this work, we have calculated a wealth of accurate MRCI energies for the first singlet state of the methylene biradical, which have subsequently been corrected using the DMBE-SEC method and modeled analytically using DMBE theory. The global DMBE PES so obtained shows good behavior over the entire configuration space. Its various topographical features have also been carefully examined and compared with the corresponding attributes of other PESs, as well as experimental data available in the literature. The good agreement observed

with the rate constant values reported in the literature recommends it for future dynamics studies of the title reaction.
